## INTRODUCTION

A detailed till sampling program around known mineral occurrences began in 1982 as part of the joint Canada-Manitoba Interim Mineral Development Agreement. One of the areas studied in detail was the Agassiz Metallotect extending east from the MacLellan Mine (Agassiz deposit) to Nickel Lake (Fig. 1). The primary objective of the till sampling was to map till geochemical anomalies in this area of little outcrop to aid mineral exploration.

It is the purpose of this report to present the geochemical data and the preliminary interpretations of the trace element geochemistry on the till samples from this region. No attempt has been made to contour the geochemical data, and interpretation is kept to a minimum as the pebble counts and the mineralogical, textural, and geochemical analyses are incomplete.

## BEDROCK GEOLOGY

The Minton Lake-Nickel Lake area is part of the northern belt of the Archean Lynn Lake greenstone belt. The northern belt comprises a monoclinical sequence of interlayered Wasekwan Group tholeiitic and high alumina mafic and intermediate volcanic rocks, coarse to fine grained paragneiss, greywacke and conglomerate. A thin but persistent oxide, sulphide and silicate facies iron formation interbedded with a distinctive tholeiitic picrite (Fox and Johnson, 1981) occurs within the stratigraphy east of the Agassiz Au-Ag deposit. This marker sequence, which apparently correlates with the host rocks at the Agassiz deposit to the west (i.e. the Agassiz Metallotect), continues eastward to Nickel Lake and Barrington Lake thickening considerably at Farley Lake.

The volcanic and sedimentary rocks in the Minton Lake-Nickel Lake area have been intruded by small subvolcanic plutons that range in composition from tonalite to diorite. Metamorphism in this portion of the belt attained upper greenschist to middle amphibolite conditions.

## SURFICIAL GEOLOGY

The area lies entirely within the area dominated by ice flow from the Keewatin Sector of the Laurentide Ice Sheet. The main ice flow direction ranged between  $180^{\circ}$  and  $225^{\circ}$ . It was this ice flow that deposited most of the till exposed at the surface and near surface along the Agassiz Metallotect. A younger ice flow toward the southeast is believed to have been in response to late glacial readjustment of the ice margin during deglaciation. The younger ice flow did not significantly affect the western part of the area. In the Farley Lake-Nickel Lake area, however, the effect of the youngest flow is more pronounced than to the west but it is uncertain what effect, if any, it had on the till provenance.

A detailed description of the surficial sediments in the region is given by Nielsen and Graham (1985).

## METHODS

A total of 810 hand-dug holes each about 1 m deep were put down along the Agassiz Metallotect between the Agassiz Au-Ag deposit and Nickel Lake (Figs. 2A, 2B, 2C). The results from an additional 216 holes dug in the Farley Lake area were reported previously (Nielsen and Graham, 1985).

The samples were collected approximately 100 m apart along the vertical field gradiometer anomaly (Barrington Lake area, Questor INPUT Survey Map, 1977) where till outcrops (Figs. 3A, 3B, 3C). Bedrock was reached in 118 holes. Samples consisted of from 5 to 10 kg of grey, generally unoxidized till.

Two fractions, a heavy mineral concentrate with specific gravity greater than 2.96 and a clay sized fraction less than 2 microns in diameter, were separated and submitted for trace element geochemistry (Fig. 4). The clay sized fraction was concentrated from a 500 gm split in the Manitoba Energy and Mines Laboratory in Winnipeg. The heavy mineral concentrates and visible gold grain counts were done under contract to Overburden Drilling Co.

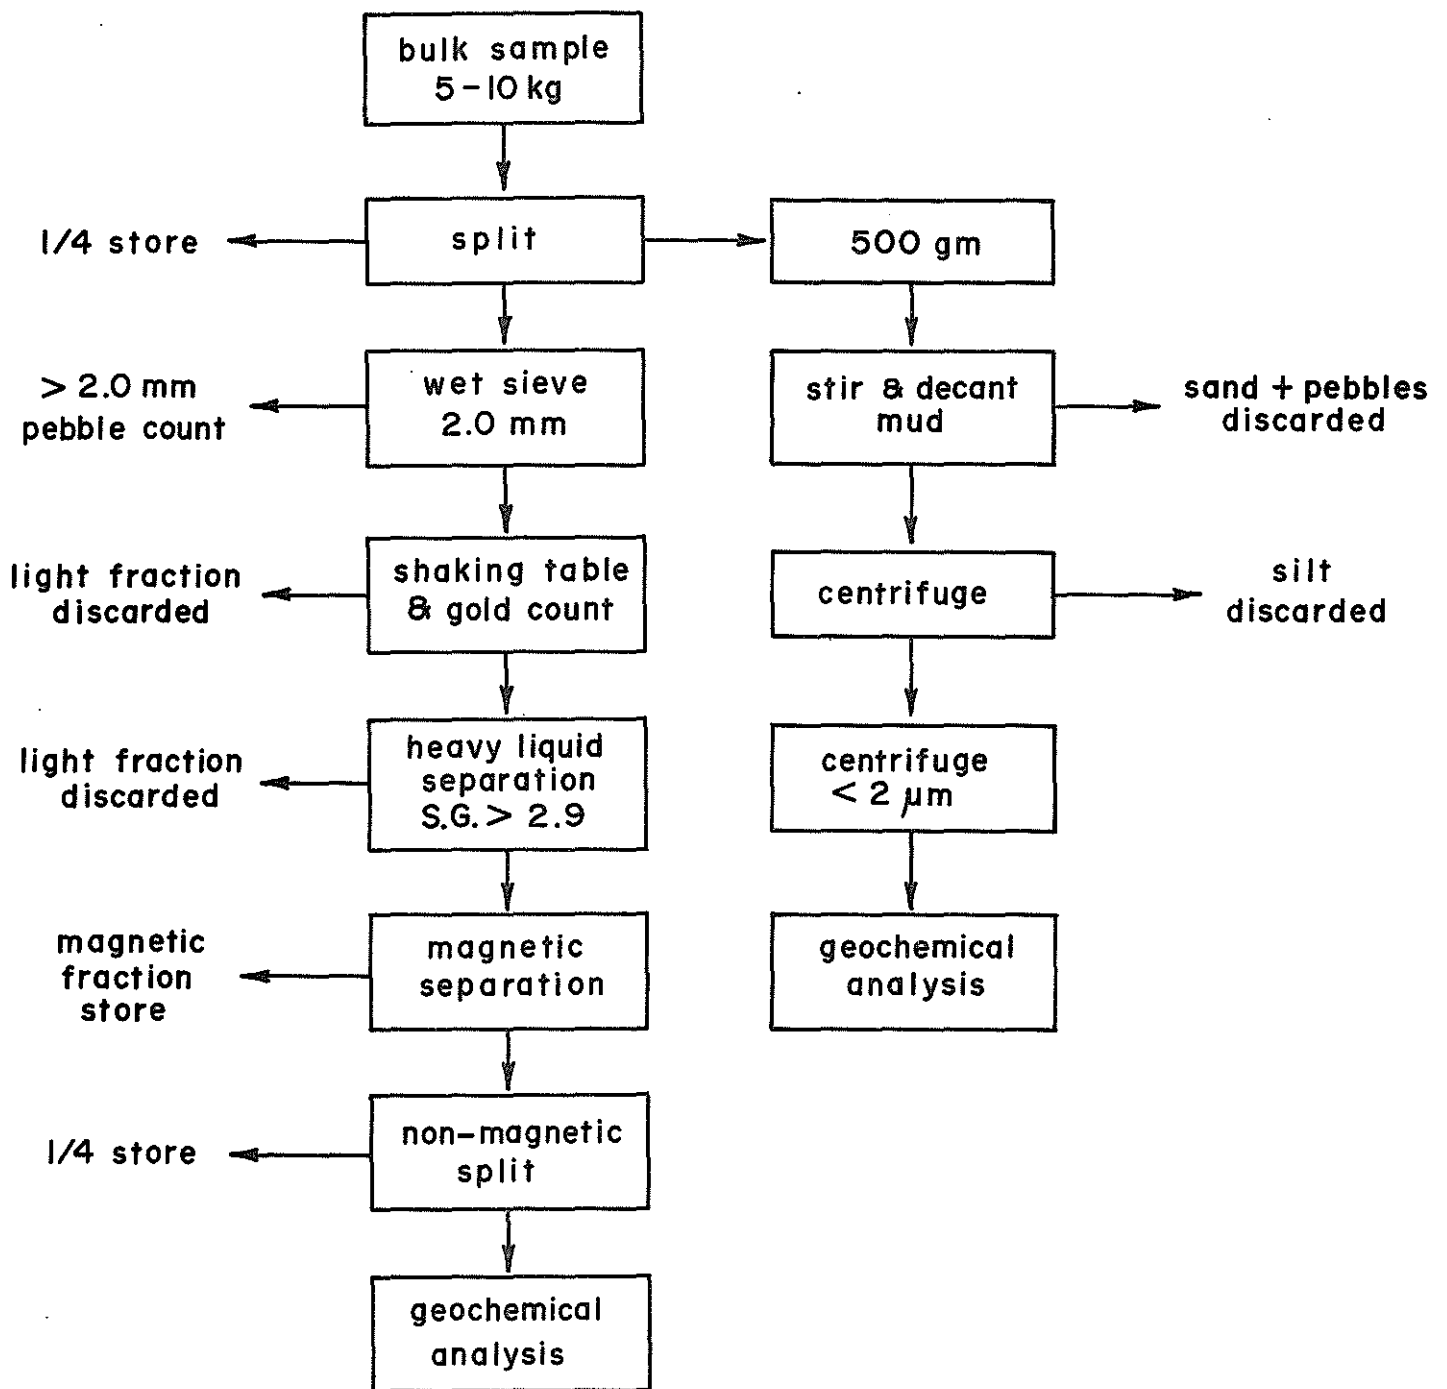

Figure 4: Sample processing flow sheet for till samples.

Ltd. in Ottawa. Gold and arsenic analyses were done under contract to Bondar-Clegg & Co. Ltd. in Ottawa, and the remaining analyses were done in the Manitoba Energy and Mines Analytical Laboratory.

The clay sized fraction of the samples received no prior treatment but the heavy mineral fraction was pulverized to -200 mesh. Cu, Pb, Zn, Ni, Co, Cr, Fe and Mn were analyzed by atomic absorption spectrophotometry after hot nitric-hydrochloric acid extraction. Arsenic was analyzed colorimetrically after nitric-perchloric acid digestion. Gold in the heavy mineral fraction was analyzed by fire assay and atomic absorption using an approximately 20 gm sample.

The lower detection limits for all the elements is 1 or 2 ppm, except Fe and Au which have lower detection limits of 0.1 per cent and 5 ppb, respectively. The lower detection limit of Au was 2 ppb for the samples collected in 1982.

## RESULTS

The geochemical data and the gold counts are listed in Appendix I. The frequency distribution of the ten elements is shown in Figure 5 and the summary statistics are listed in Table 1. Threshold values for each element have been determined by plotting cumulative frequency diagrams with a probability scale (Fig. 6).

Several multi-sample anomalies with gold values above 15 ppb coincident with visible gold occurrences are found in the area. These areas are locally coincident with high arsenic values in the clay sized fraction although arsenic does not correlate well with gold in the heavy mineral fraction (Table 2). The presence of visible gold in a till sample, as well as the size and physical characteristics of the gold grains in conjunction with geochemical analysis of the heavy mineral fraction, are the best indicators of nearby gold mineralization.

Table 1. Summary statistics for the geological data.

Variable:	Cu	Pb	Zn	Ni	Co	Cr	Fe	Mn	As	Au

## DISCUSSION

A glacial dispersion train 1.5 km long has been mapped near Dot Lake west of Keewatin River using arsenic in the clay sized fraction and gold in the heavy mineral fraction. The dispersion train associated with the Agassiz Au-Ag deposit on the east side of the Keewatin River is, however, only about 150 m long (Nielsen, in prep.). The difference in the length of these two dispersion trains is believed to be the result of distinct outcrop patterns of the mineralization with respect to the local topography. The Agassiz mineralization outcrops toward the lee side of a hill and the Dot Lake mineralization outcrops near the crest of a hill. Consequently the Dot Lake mineralization was exposed to glacial erosion whereas the Agassiz mineralization was more protected. The role of the topography is considered an important factor in evaluating dispersion trains and distances of glacial transport along the Agassiz Metallotect.

The 'patchy' nature of gold and arsenic anomalies may be due to sampling from relatively shallow hand-dug holes. Although the till sheet is generally thin, anomalies might be enhanced by sampling directly above the bedrock. For example, in the Nickel Lake area 29 of the 50 holes terminated on bedrock. This is a higher proportion than anywhere to the west and arsenic values are higher in this area than anywhere else. It is not known whether the high arsenic values are related to the shallow drift at Nickel Lake or to higher concentrations of arsenic in the bedrock. Indications at Dot Lake and at the Agassiz deposit are that the sampling depth is not an important variable in delineating the dispersion train.

The visible gold grains are mainly abraded and irregular in shape (Table 3) indicating they have undergone at least some glacial transport. Based on their distribution down ice from the Agassiz and Dot Lake mineralization, visible gold grains do not appear to travel more than a few hundred metres from their source.

Table 3. Characteristics of visible gold grains from till samples.
